Abstract

• Although we use our visual and tactile sensory systems interchangeably daily, little is known about the mechanism underlying this ability.

• The ability to recognize objects in both sensory modalities brings up two main questions:
  1- How do humans build up representations of their surroundings using visual or tactile system?
  2- Which common features describe the properties of human perceptions that mediate interchangeability between visual and tactile modalities?

• In this study on both sexes of human participants, we examined how 3D shape features of objects form two congruent and interchangeable visual and tactile perceptual spaces.

Fit values for combinations of feature (F1–F17)

To investigate which object features constituted the highly compatible perceptual spaces, seventeen features were extracted such as, Gaussian curvature, volume of objects, inertia tensor.
Results / Conclusions

• Our results indicate even for unfamiliar objects that in the absence of visual perception, a tactile inspection is capable of recovering the same perceptual space as the visual system, and vice versa.
• In addition to the highly congruent perceptual spaces of both visual and tactile exploration, the two clusters represent the two object categories of the VP algorithm.
• We have shown that the visual and tactile sensory systems share common features to identify objects.
• The existence of such a multimodal perceptual mechanism might be the main reason why humans can interchangeably use visual and tactile modalities because the acquired object information can be shared or transferred between modalities.
• Also, our results indicate a link between perceptual spaces of visual and tactile systems which can lead to the assumption that both modalities use a similar cognitive process to represent the shape information.
